#### Abstract

We report a measurement of the proton-air cross-section for particle production at the center-ofmass energy per nucleon of 57 TeV . This is derived from the distribution of the depths of shower maxima observed with the Pierre Auger Observatory: systematic uncertainties are studied in detail. Analysing the tail of the distribution of the shower maxima, a proton-air cross-section of $\left[505 \pm 22\right.$ (stat) ${ }_{-36}^{+28}($ sys $\left.)\right] \mathrm{mb}$ is found.

PACS numbers:

## INTRODUCTION

We present the first analysis of the proton-air crosssection based on measurements made at the Pierre Auger Observatory [1]. For this purpose we analyse the shape of the distribution of the largest values of the depth of shower maximum, $X_{\text {max }}$, the position at which an air shower deposits the maximum energy per unit of mass of atmosphere traversed. The tail of the $X_{\max }$-distribution is sensitive to the proton-air cross-section, a fact first exploited in the pioneering work of the Fly's Eye Collaboration [2]. To obtain accurate measurements of $X_{\max }$, timing data from the fluorescence telescopes is combined with that from the surface detector array for a precise hybrid reconstruction of the geometry of events [3].

We place particular emphasis on studying systematic uncertainties in the cross-section analysis. The unknown mass composition of cosmic-rays 4] is identified to be the major source of systematic uncertainty and accordingly the analysis has been optimised to minimise the impact of particles other than protons in the primary beam. This begins with restricting the analysis to the energy interval $10^{18}$ to $10^{18.5} \mathrm{eV}$, where the shape of the $X_{\max }$-distribution is compatible with there being a substantial fraction of protons; also there are a large number of events recorded in this energy range. The corresponding average center-of-mass energy of a proton interacting with a nucleon is 57 TeV , significantly above the reach of the Large Hadron Collider.

## ANALYSIS APPROACH

The proton-air cross-section is derived in a two-step process. Firstly, we measure an air-shower observable with high sensitivity to the cross-section. Secondly, we convert this measurement to a value of the proton-air cross-section for particle production (c.f. [5]). This is the cross-section that accounts for all interactions which produce particles and thus contribute to the air-shower development; it implicitly also includes diffractive interactions. As the primary observable we define $\Lambda_{\eta}$ via the exponential shape of the tail of the $X_{\max }$-distribution, $\mathrm{d} N / \mathrm{d} X_{\max } \propto \exp \left(-X_{\max } / \Lambda_{\eta}\right)$, where $\eta$ denotes the fraction of most deeply penetrating air showers used. Considering only these events enhances the contribution of
protons in the sample, since the depth at which protoninduced showers maximise is deeper in the atmosphere than for showers from heavier nuclei. Thus, $\eta$ is a key parameter: a small value enhances the proton fraction, but reduces the number of events available for the analysis. We have chosen $\eta=0.2$ so that, for helium-fractions up to $25 \%$, biases introduced by the possible presence of helium and heavier nuclei do not exceed the level of the statistical uncertainty. This was chosen after a Monte Carlo study that probed the sensitivity of the analysis to the mass composition depending on the choice of different values of $\eta$.

## THE MEASUREMENT OF $\Lambda_{\eta}$

We use events collected between 1 Dec 2004 and 20 Sept 2010. The atmospheric and event-quality cuts applied are identical to those used for the analysis of $\left\langle X_{\max }\right\rangle$ and $\operatorname{RMS}\left(X_{\max }\right)$ [6] yielding 11628 high-quality events. The $X_{\max }$-distribution of these data is affected by the known geometrical acceptance of the fluorescence telescopes as well as by limitations related to atmospheric light transmission. We use the strategy developed for the measurement of $\left\langle X_{\max }\right\rangle$ and $\mathrm{RMS}\left(X_{\max }\right)$ to extract a sample that has an unbiased $X_{\text {max }}$-distribution: a fiducial volume selection, which requires event geometries that allow, for each individual shower, the complete observation of a defined slant depth range.

Firstly, we derive the range of values of $X_{\max }$ that corresponds to the fraction $\eta=0.2$ of the most deeply penetrating showers. For this we need an unbiased distribution of $X_{\max }$ over the entire depth range of observed values of $X_{\max }$. To achieve this we perform a fiducial event selection of the slant depth range containing $99.8 \%$ of the observed $X_{\max }$-distribution, which corresponds to the range from 550 to $1004 \mathrm{~g} / \mathrm{cm}^{2}$. This reduces the data sample to 1635 events providing an unbiased $X_{\text {max }^{-}}$ distribution that is used to find the range of values of $X_{\max }$ corresponding to $\eta=0.2$, identified to extend from 768 to $1004 \mathrm{~g} / \mathrm{cm}^{2}$.

Secondly, we select those events from the original 11628 that have geometries allowing the complete observation of values of $X_{\max }$ from 768 to $1004 \mathrm{~g} / \mathrm{cm}^{2}$, the tail of the unbiased distribution. This fiducial cut maximises the statistics of an unbiased $X_{\max }$-distribution in

FIG. 1: Unbinned likelihood fit to obtain $\Lambda_{\eta}$ (thick line). The $X_{\text {max }}$-distribution is unbiased by the fiducial geometry selection applied in the range of the fit.
the range of interest. In total 3082 events pass the fiducial volume cuts, of which 783 events have their $X_{\max }$ in the selected range and thus contribute directly to the measurement of $\Lambda_{\eta}$. In Fig. [1 we show the 3082 selected events and the result of an unbinned maximum likelihood fit of an exponential function over the range 768 to $1004 \mathrm{~g} / \mathrm{cm}^{2}$. Values of $\Lambda_{\eta}$ have been re-calculated for subsamples of the full dataset selected according to zenithangle, shower-to-telescope distance and energy: the different values obtained for $\Lambda_{\eta}$ are consistent with statistical fluctuations. The re-analyses of the data for changes of fiducial event selection, modified values of $\eta$ and for different ranges of atmospheric depths yield changes of $\Lambda_{\eta}$ that are distributed around zero with a root-meansquare of $1.6 \mathrm{~g} / \mathrm{cm}^{2}$. We use this root-mean-square as an estimate of the systematic uncertainties associated to the measurement. This yields

$$
\begin{equation*}
\Lambda_{\eta}=[55.8 \pm 2.3(\mathrm{stat}) \pm 1.6(\mathrm{sys})] \mathrm{g} / \mathrm{cm}^{2} \tag{1}
\end{equation*}
$$

with the average energy of these events being $10^{18.24} \pm 0.005$ (stat) eV . The differential energy distribution for these events follows a power-law with index -1.9 . The average energy corresponds to a center-of-mass energy of $\sqrt{s}=[57 \pm 0.3$ (stat) $] \mathrm{TeV}$ in proton-proton collisions.

## DETERMINATION OF THE CROSS-SECTION

The determination of the proton-air cross-section for particle production requires the use of air-shower simulations, which inherently introduces some dependence on model assumptions. We emulate the measurement of $\Lambda_{\eta}$ with Monte Carlo simulations to derive predictions of the slope, $\Lambda_{\eta}^{\mathrm{MC}}$. It is known from previous work that the values of $\Lambda_{\eta}^{\mathrm{MC}}$ are directly linked to the hadronic crosssections used in the simulations [2]. Accordingly we can
explore the effect of changing cross-sections empirically by multiplying all hadronic cross-sections input to the simulations by an energy-dependent factor 7]

$$
\begin{equation*}
f\left(E, f_{19}\right)=1+\left(f_{19}-1\right) \frac{\lg \left(E / 10^{15} \mathrm{eV}\right)}{\lg \left(10^{19} \mathrm{eV} / 10^{15} \mathrm{eV}\right)} \tag{2}
\end{equation*}
$$

where $E$ denotes the shower energy and $f_{19}$ is the factor by which the cross-section is rescaled at $10^{19} \mathrm{eV}$. This factor is unity below $10^{15} \mathrm{eV}$ reflecting the fact that measurements of the cross-section at the Tevatron were used to tune the interaction models. This technique of modifying the original predictions of the cross-sections during the simulation process assures a smooth transition from accelerator data up to the energies of our analysis.

For each hadronic interaction model, the value of $f_{19}$ is obtained that reproduces the measured value of $\Lambda_{\eta}$. The modified cross-section is then deduced by multiplying the original cross-section used in the model by the factor $f\left(E, f_{19}\right)$ of Eq. (2) using $E=10^{18.24} \mathrm{eV}$. For the conversion of $\Lambda_{\eta}$ into cross-section, we have used the four highenergy hadronic interaction models commonly adopted for air shower simulations: QGSJet01 [8], QGSJetII.3 [9], SIBYLL 2.1 [10] and EPOS1.99 [11]. While in general no model gives a completely accurate representation of cosmic-ray data in all respects, these have been found to give reasonably good descriptions of many of the main features. It has been shown [12] that the differences between the models used in the analysis are typically bigger than the variations obtained within one model by parameter variation. Therefore we use the model differences for estimating the systematic model dependence.

The proton-air cross-sections for particle production derived for QGSJet01, QGSJetII, SIBYLL and EPOS are $523.7,502.9,496.7$ and 497.7 mb respectively, with the statistical uncertainty for each of these values being 22 mb . The difference of these cross-sections from the original model predictions are $<5 \%$, with the exception of the result obtained with the SIBYLL model, which is $12 \%$ smaller than the original SIBYLL prediction. We use the maximum deviations derived from using the four models, relative to the average result of 505 mb , to estimate a systematic uncertainty of $(-8,+19) \mathrm{mb}$ related to the difficulties of modelling high energy interactions. This procedure relies on the coverage of the underlying theoretical uncertainties by the available models. For example diffraction, fragmentation, inelastic intermediate states, nuclear effects, QCD saturation, etc. are all described at different levels using different phenomenological, but self-consistent, approaches in these models. It is thus possible that the true range of the uncertainties for air-shower analyses is larger, but this cannot be estimated with these models. Furthermore, certain features of hadronic particle production, such as the multiplicity, elasticity and pion-charge ratio, have an especially important impact on air shower development 13, 14; of
these we found that only the elasticity can have a relevant impact on $\Lambda_{\eta}$. The previously identified systematic uncertainty of $(-8,+19) \mathrm{mb}$ induced by the modelling of hadronic interactions, corresponds to the impact of modifying the elasticity within $\pm(10-25) \%$ in the models.

The selection of events with large values of $X_{\max }$ also enhances the fraction of primary cosmic-ray interactions with smaller multiplicities and larger elasticities, which is for example characteristic for diffractive interactions. The value of $\Lambda_{\eta}$ is thus more sensitive to the cross-section of those interactions. The identified model-dependence for the determination of $\sigma_{p \text {-air }}^{\text {prod }}$ is also caused by the compensation of this effect.

Also the choice of a logarithmic energy dependence for the rescaling-factor in Eq. (2) may affect the resulting cross-sections. However, since the required rescalingfactors are small, this can only be a marginal effect.

The systematic uncertainty of $22 \%$ 15 in the absolute value of the energy scale leads to systematic uncertainties of 7 mb in the cross-section and 6 TeV in the center-ofmass energy. Furthermore, the procedure to obtain $\sigma_{p \text {-air }}^{\text {prod }}$ from the measured $\Lambda_{\eta}$ depends on additional parameters. By varying the energy distribution, energy and $X_{\max }$ resolution in the simulations, we find that related systematic changes of the value of $\sigma_{p \text {-air }}^{\text {prod }}$ are distributed with a root-mean-square of 7 mb around zero. We use the root-mean-square as estimate of the systematic uncertainties related to the conversion of $\Lambda_{\eta}$ to $\sigma_{p-\mathrm{air}}^{\mathrm{prod}}$.

The presence of photons in the primary beam would bias the measurement. The average $X_{\max }$ of showers produced by photons at the energies of interest is about $50 \mathrm{~g} / \mathrm{cm}^{2}$ deeper in the atmosphere than that of protons. However, observational limits on the fraction of photons are $<0.5 \%$ [16, 17]. With simulations we find that the possible under-estimation of the cross-section if photons were present in the data sample at this level is less than 10 mb .

With the present limitations of observations, we cannot distinguish air showers produced by helium nuclei from those created by protons. From simulations we find

TABLE I: Summary of the systematic uncertainties.

| Description | Impact on $\sigma_{p \text {-air }}^{\text {prod }}$ |
| :--- | ---: |
| $\Lambda_{\eta}$ systematics | $\pm 15 \mathrm{mb}$ |
| Hadronic interaction models | ${ }_{-8}^{+19} \mathrm{mb}$ |
| Energy scale | $\pm 7 \mathrm{mb}$ |
| Conversion of $\Lambda_{\eta}$ to $\sigma_{p \text {-air }}^{\text {prod }}$ | $\pm 7 \mathrm{mb}$ |
| Photons, $<0.5 \%$ | $<+10 \mathrm{mb}$ |
| Helium, $10 \%$ | -12 mb |
| Helium, $25 \%$ | -30 mb |
| Helium, $50 \%$ | -80 mb |
| Total $(25 \%$ helium $)$ | $-36 \mathrm{mb},+28 \mathrm{mb}$ |

FIG. 2: Resulting $\sigma_{n_{n} \text { air }}^{\text {prod }}$ compared to other measurements (see [18-20, 30-34] for references) and model predictions. The inner error bars are statistical, while the outer include systematic uncertainties for a helium fraction of $25 \%$ and 10 mb for the systematic uncertainty attributed to the fraction of photons.
that $\sigma_{p \text {-air }}^{\text {prod }}$ is over-estimated depending on the percentages of helium in the data sample. Lack of knowledge of the helium fraction is the dominant source of systematic uncertainty.

We also find that the nuclei of the CNO-group introduce no bias for fractions up to $\sim 50 \%$, and accordingly we assign no uncertainty in the cross-section due to these or heavier nuclei.

In Table $\mathbb{\square}$ we list the sources of systematic uncertainties. As the helium fraction is not known we show the impact of 10,25 and $50 \%$ of helium respectively. In what follows we include a systematic uncertainty related to a helium fraction of $25 \%$. In the extreme case, were the cosmic-ray composition to be $100 \%$ helium, the analysis would over-estimate the proton-air cross-section by 300 to 500 mb . Given the constraints from accelerator data at lower energies and typical model assumptions, this extreme scenario is not realistic.

We summarise our results by averaging the four values of the cross-section obtained with the hadronic interaction models to give

$$
\sigma_{p-\text { air }}^{\text {prod }}=\left[505 \pm 22(\text { stat })_{-36}^{+28}(\mathrm{sys})\right] \mathrm{mb}
$$

at a center-of-mass energy of $[57 \pm 0.3$ (stat) $\pm$ 6 (sys) ] TeV. In Fig. 2 we compare this result with model predictions and other measurements. The measurements at the highest energies are: HiRes [18] and Fly's eye 2] that are both based on $X_{\max }$, Yakutsk Array [19] using Cherenkov observations and Akeno 20] measuring electron and muon numbers at ground level. All these analyses assume a pure proton composition. In the context of a possible mixed-mass cosmic-ray composition, this can lead to large systematic effects. Also all these analyses are based on a single interaction model for describing air
showers: Only HiRes uses a second model for systematic checks.

It is one of the prime aims of our analysis to have the smallest possible sensitivity to a non-proton component, and to perform a detailed systematic analysis on the uncertainties related to the mass composition. We also use, for the first time, all hadronic interaction models currently available for the estimation of model-related systematic effects. Futhermore, by using Eq. (2) we derive a cross-section corresponding to a smooth interpolation from the Tevatron measurement to our analysis, with no inconsistencies as in earlier approaches.

## COMPARISON WITH ACCELERATOR DATA

For the purpose of making comparisons with accelerator data we calculate the inelastic and total protonproton cross-sections using the Glauber model. We use standard Glauber formalism 21], extended by a two-channel implementation of inelastic intermediate states [8] to account for diffraction dissociation [22]. The first channel corresponds to $p \rightarrow p$ scattering and has an amplitude of $\Gamma_{p p}$, while the amplitude for the other channel is $\Gamma_{p p^{*}}=\lambda \Gamma_{p p}$ and corresponds to the excitation of a short lived intermediate state. The parameter $\lambda$ is related to the ratio of single-diffractive cross-section and elastic cross-section. We use a value of $\lambda=0.5 \pm 0.15$ that is determined from measurements of the single-diffractive cross-section, as well as from proton-carbon cross-section data at lower energies.

This Glauber calculation is model-dependent since neither the parameters nor the physical processes involved

FIG. 3: Correlation of elastic slope parameter, $B_{\mathrm{el}}$, and the inelastic proton-proton cross-section in the Glauber framework. The solid line indicates the parameter combinations yielding the observed proton-air production cross-section, and the dotted lines are the statistical uncertainties. The hatched area corresponds to the predictions by SIBYLL, QGSJet, QGSJetII and EPOS. See also Ref. [5].
are known accurately at cosmic-ray energies. In particular, this applies to the elastic slope parameter, $B_{\mathrm{el}}$, (defined by $\mathrm{d} \sigma_{\text {el }} / \mathrm{d} t \propto \exp \left(-|t| B_{\text {el }}\right)$ for very small $t$ ), the correlation of $B_{\mathrm{el}}$ to the cross-section, and the cross-section for diffractive dissociation. For the example of $\sigma_{p p}^{\text {inel }}$, the correlation of $B_{\text {el }}$ with the cross-section is shown in Fig. 33 for $\lambda=0.5$. We have used the same four hadronic interaction models to determine the uncertainty band of the $B_{\text {el }}-\sigma_{p p}^{\text {inel }}$ correlation. Recent cross-section models such as [23] fall within this band. We find that in the Glauber framework the inelastic cross-section is less dependent on model assumptions than the total cross-section. The result for the inelastic proton-proton cross-section is

$$
\sigma_{p p}^{\text {inel }}=\left[92 \pm 7(\text { stat }){ }_{-11}^{+9}(\text { sys }) \pm 7(\text { Glauber })\right] \mathrm{mb}
$$

and the total proton-proton cross-section is

$$
\sigma_{p p}^{\mathrm{tot}}=\left[133 \pm 13(\text { stat }){ }_{-20}^{+17}(\text { sys }) \pm 16(\text { Glauber })\right] \mathrm{mb}
$$

The systematic uncertainties for the inelastic and total cross-sections include contributions from the elastic slope parameter, from $\lambda$, from the description of the nuclear density profile, and from cross-checking these effects using QGSJetII [9, 24]. For the inelastic case, these three independent contributions are $1,3,5$, and 4 mb respectively. For the total cross-section, they are $13,6,5$, and 4 mb . We emphasize that the total theoretical uncertainty of converting the proton-air to a proton-proton cross-section may be larger than estimated here within the Glauber model. There are other extensions of the Glauber model to account for inelastic screening [8, 25] or nucleon-nucleon correlations [26], and alternative approaches that include, for example, parton saturation or other effects 11, 24, 27, 28].

In Fig. 4 we compare our inelastic cross-section result to accelerator data and to the cross-sections used in the hadronic interaction models.

## SUMMARY

We have presented the first measurement of the crosssection for the production of particles in proton-air collisions from data collected at the Pierre Auger Observatory. We have studied in detail the effects of assumptions on the primary cosmic-ray mass composition, hadronic interaction models, simulation settings and the fiducial volume limits of the telescopes on the final result. By analysing only the most deeply penetrating events we selected a data sample enriched in protons. The results are presented assuming a maximum contamination of $25 \%$ of helium in the light cosmic-ray mass component. The lack of knowledge of the helium component is the largest source of systematic uncertainty. However, for helium fractions up to $25 \%$ the induced bias remains below $6 \%$.

To derive a value of $\sigma_{p \text {-air }}^{\text {prod }}$ from the measured $\Lambda_{\eta}$ we assume a smooth extrapolation of hadronic cross-sections

FIG. 4: Comparison of derived $\sigma_{p p}^{\text {inel }}$ to model predictions and accelerator data 29]. Here we also show the cross-sections of two typical high-energy models, Pythia6 [35] and Phojet [36]. The inner error bars are statistical, while the outer include systematic uncertainties.
from accelerator measurements to the energy of the analysis. This is achieved by modifying the model-predictions of hadronic cross-sections above energies of $10^{15} \mathrm{eV}$ during the air-shower simulation process in a self-consistent approach.

We convert the proton-air production cross-section into the total, and the inelastic, proton-proton crosssection using a Glauber calculation that includes intermediate inelastic screening corrections. In this calculation we use the correlation between the elastic slope parameter and the proton-proton cross-sections taken from the interaction models as a constraint. We find that the inelastic proton-proton cross-section depends less on the elastic slope parameter than does the total proton-proton cross-section, and thus the systematic uncertainty of the Glauber calculation for the inelastic result is smaller. The data agree with an extrapolation from LHC 29] energies to 57 TeV for a limited set of models.
Acknowledgments. The successful installation, commissioning, and operation of the Pierre Auger Observatory would not have been possible without the strong commitment and effort from the technical and administrative staff in Malargüe.
